Outline

- ① Process model
- ② Process state diagram
- ③ Process control table
- ④ Context switching
- ⑤ Threads and multithreading
- ⑥ Bibliography

Process

Execution in a multiprogrammed environment

Processes

Process model

- In **multiprogramming** the **activity of the processor**, because it is switching back and forth from process to process, **is hard to perceive**
- Thus, it is better to assume the **existence of a number of virtual processors, one per existing process**
 - **Turning off one virtual processor and on another, corresponds to a process switching**
 - **number of active virtual processors \leq number of real processors**

Processes

Process model (2)

- The switching between processes, and thus the switching between virtual processors, can occur for different reasons, possibly not controlled by the running program
- Thus, to be viable, this process model requires that
 - the execution of any process is not affected by the instant in time or the location in the code where the switching takes place
 - no restrictions are imposed on the total or partial execution times of any process

Processes

(Short-term) Process states

- A process can be not running for different reasons
 - so, one should identify the possible process states
- The most important are:
 - **RUN** – the process is in possession of a processor, and thus running
 - **BLOCKED** – the process is waiting for the occurrence of an external event (access to a resource, end of an input/output operation, etc.)
 - **READY** – the process is ready to run, but waiting for the availability of a processor to start/resume its execution
- Transitions between states usually result from external intervention, but, in some cases, can be triggered by the process itself
- The part of the operating system that handles these transitions is called the (processor) scheduler, and is an integral part of its kernel
 - Different policies exist to control the firing of these transitions
 - They will be covered later

Processes

Short-term state diagram

- **event wait** – the running process is prevented to proceed, awaiting the occurrence of an external event
- **dispatch** – one of the processes ready to run is selected and is given the processor
- **event occurs** – an external event occurred and the process waiting for it is now ready to be given the processor
- **preempt** – a higher priority process get ready to run, so the running process is removed from the processor
- **time-out** – the time quantum assigned to the running process get to the end, so the process is removed from the processor

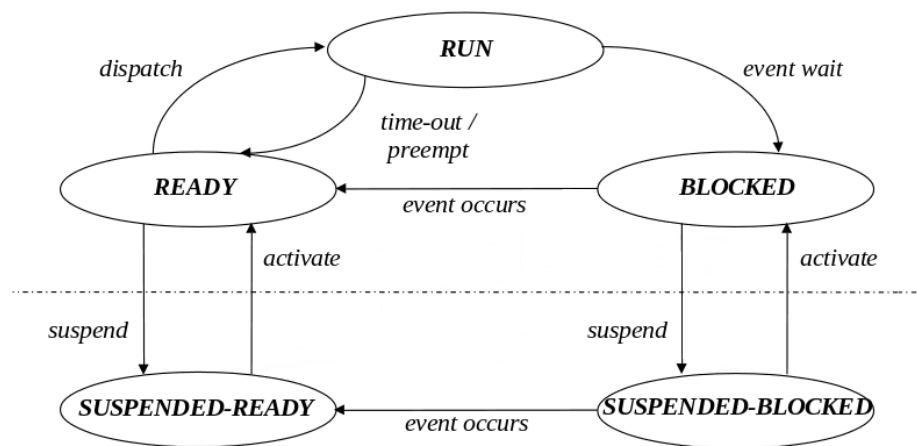

Processes

Medium-term states

- The main memory is finite, which limits the number of coexisting processes
- A way to overcome this limitation is to use an area in secondary memory to extend the main memory
 - This is called **swap area** (can be a disk partition or a file)
 - A non running process, or part of it, can be swapped out, in order to free main memory for other processes
 - That process will be later on swapped in, after main memory becomes available
- Two new states should be added to the process state diagram to incorporate these situations:
 - **suspended-ready** – the process is ready but swapped out
 - **suspended-blocked** – the process is blocked and swapped out

Processes

State diagram, including short- and medium-term states

- Two new transitions appear:
 - **suspend** – the process is swapped out
 - **activate** – the process is swapped in

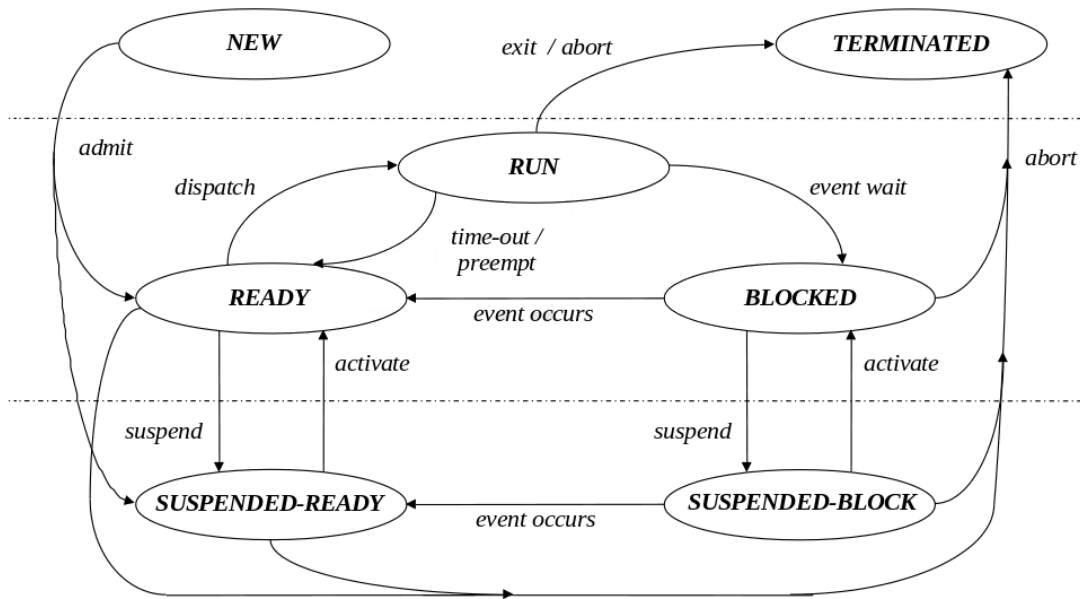

Processes

Long-term states and transitions

- The previous state diagram assumes processes are timeless
 - Apart from some system processes this is not true
 - Processes are created, exist for some time, and eventually terminate
- Two new states are required to represent creation and termination
 - **new** – the process has been created but not yet admitted to the pool of executable processes (the process data structure is been initialized)
 - **terminated** – the process has been released from the pool of executable processes, but some actions are still required before the process is discarded
- three new transitions exist
 - **admit** – the process is admitted (by the OS) to the pool of executable processes
 - **exit** – the running process indicates the OS it has completed
 - **abort** – the process is forced to terminate (because of a fatal error or because an authorized process aborts its execution)

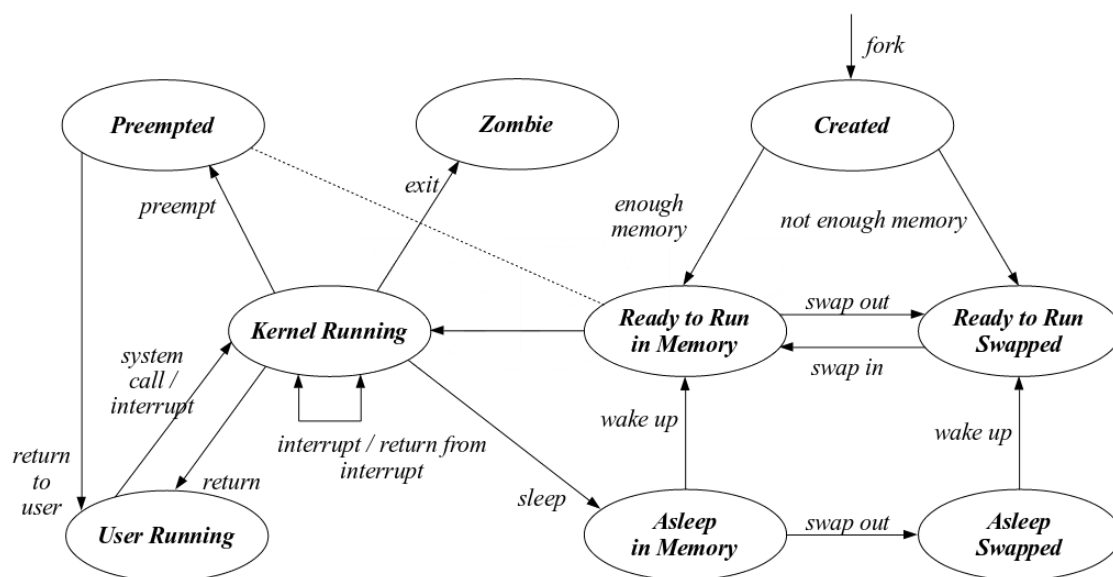

Processes

Global state diagram

Processes

Typical Unix state diagram

Processes

Typical Unix state diagram (2)

- There are two run states, **kernel running** and **user running**, associated to the **processor running mode, supervisor and user**, respectively
- The **ready state** is also splitted in two states, **ready to run in memory** and **preempted**, but they are equivalent, represented by the dashed line

Processes

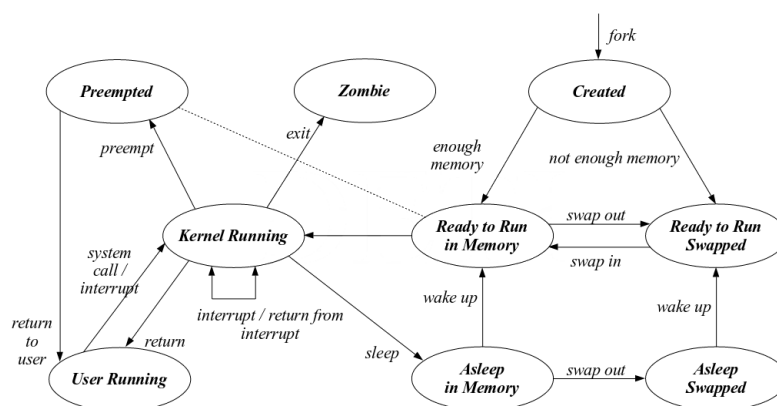

Typical Unix state diagram (3)

- When a **user process leaves supervisor mode**, it can be **preempted** (because a **higher priority process** is ready to run)
- In practice, **processes in ready to run in memory and preempted** shared the **same queue**, thus are treated as equal
- The **time-out** transition is covered by the preempt one

Processes

Typical Unix state diagram (4)

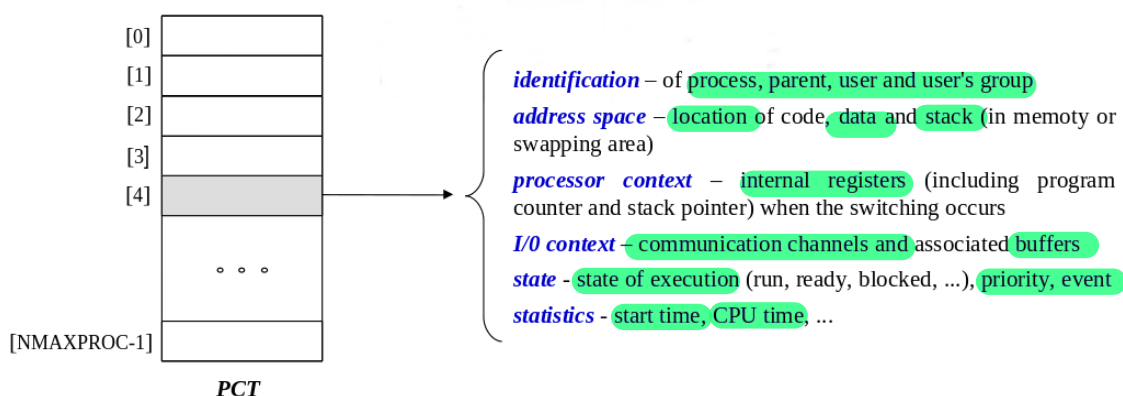

- Traditionally, execution in supervisor mode could not be interrupted (thus UNIX does not allow real time processing)
- In current versions, namely from SVR4, the problem was solved by dividing the code into a succession of atomic regions between which the internal data structures are in a safe state and therefore allowing execution to be interrupted
- This corresponds to a transition between the preempted and kernel running states, that could be called return to kernel

Processes

Process control table

- To implement the process model, the operating systems needs a data structure to be used to store the information about each process – process control block
- The process control table (PCT), which can be seen as an array of process control blocks, stores information about all processes

Processes

Context switching

- Current processors have two functioning modes:
 - **supervisor mode** – all instruction set can be executed
 - is a privileged mode
 - **user mode** – only part of the instruction set can be executed
 - input/output instructions are excluded as well as those that modify control registers
 - it is the normal mode of operation
 - Switching from user mode to supervisor mode is only possible through an exception (for security reasons)
-
- An exception can be caused by:
 - I/O interrupt
 - external to the execution of the current instruction
 - illegal instruction (division by zero, bus error)
 - associated with the execution of the current instruction, but not intended
 - trap instruction (software interruption)
 - associated with the execution of the current instruction, and intended

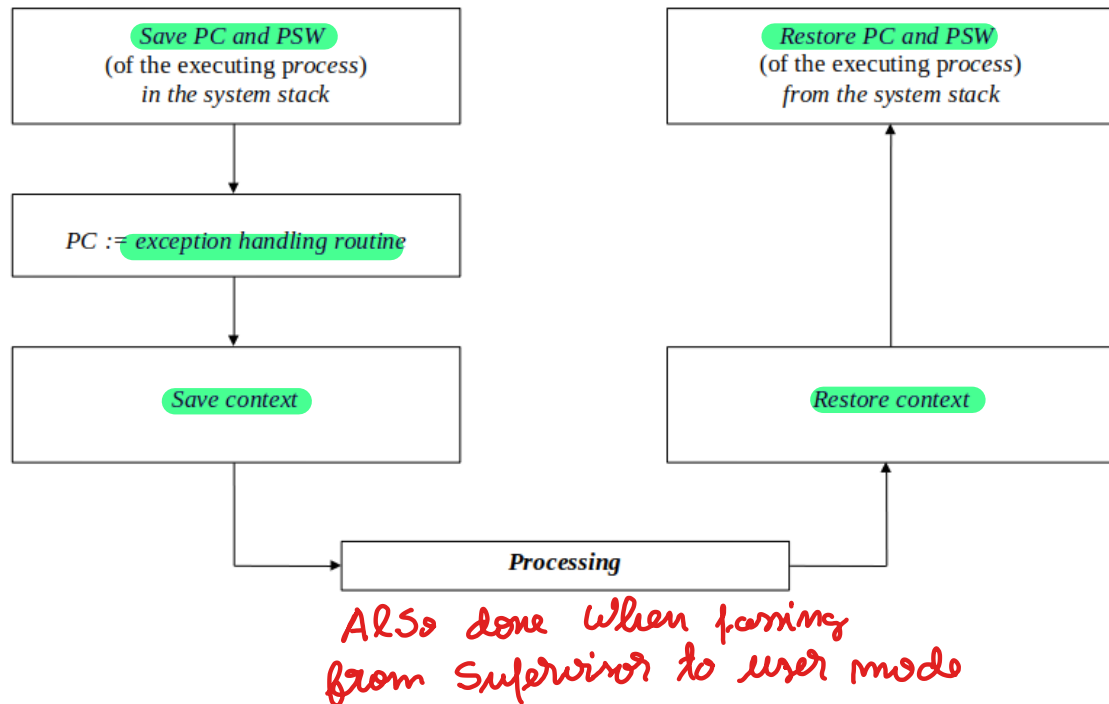

Processes

Context switching (2)

- The operating system should function in supervisor mode
 - in order to have access to all the functionalities of the processor
 - Thus kernel functions (including system calls) must be fired by
 - hardware (interrupt)
 - trap (software interruption)
 - This establishes a uniform operating environment: exception handling
-
- Context switching is the process of storing the state of a process and restoring the state of another process
 - Context switching occurs necessarily in the context of an exception, with a small difference on how it is handle

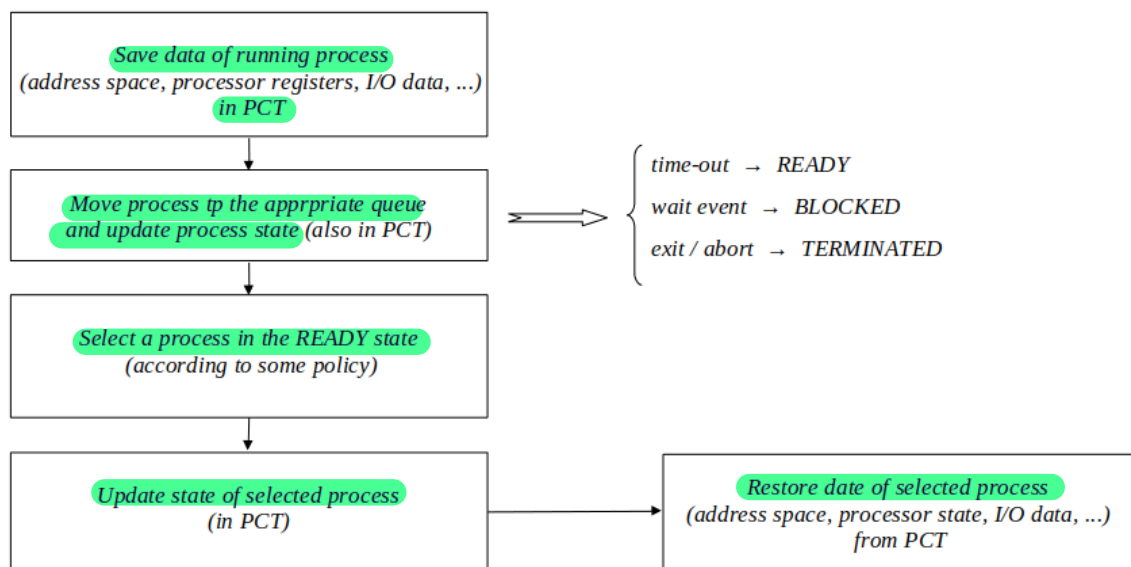

Process

Processing a (normal) exception

Process

Processing a process switching

Threads

Single threading

- In traditional operating system, a process includes:
 - an address space (code and data of the associated program)
 - a set of communication channels with I/O devices
 - a single thread of control, which incorporates the processor registers (including the program counter) and a stack
- However, these components can be managed separately
- In this model, thread appears as an execution component within a process

Threads

Multithreading

- Several independent threads can coexist in the same process, thus sharing the same address space and the same I/O context
 - This is referred to as *multithreading*
- Threads can be seen as *light weight processes*

Threads

State diagram of a thread

- Only states concerning the management of the processor are considered (short-term states)
- states **suspended-ready** and **suspended-blocked** are not present:
 - they are related to the process, not to the threads
- states **new** and **terminated** are not present:
 - the management of the multiprogramming environment is basically related to restrict the number of threads that can exist within a process
